Yigit Korkmaz: ykorkmaz@ucsd.edu

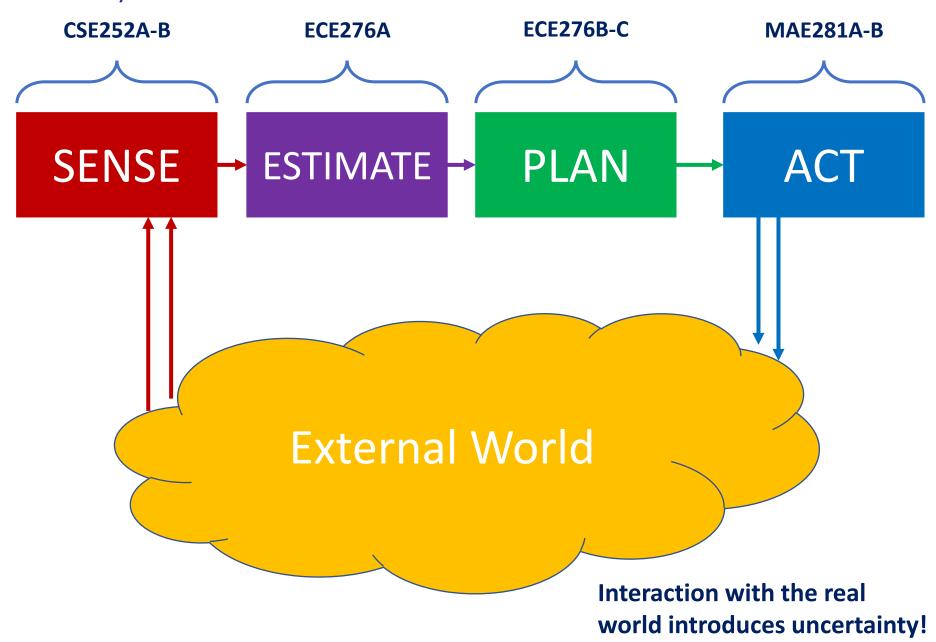

Sambaran Ghosal: sghosal@ucsd.edu

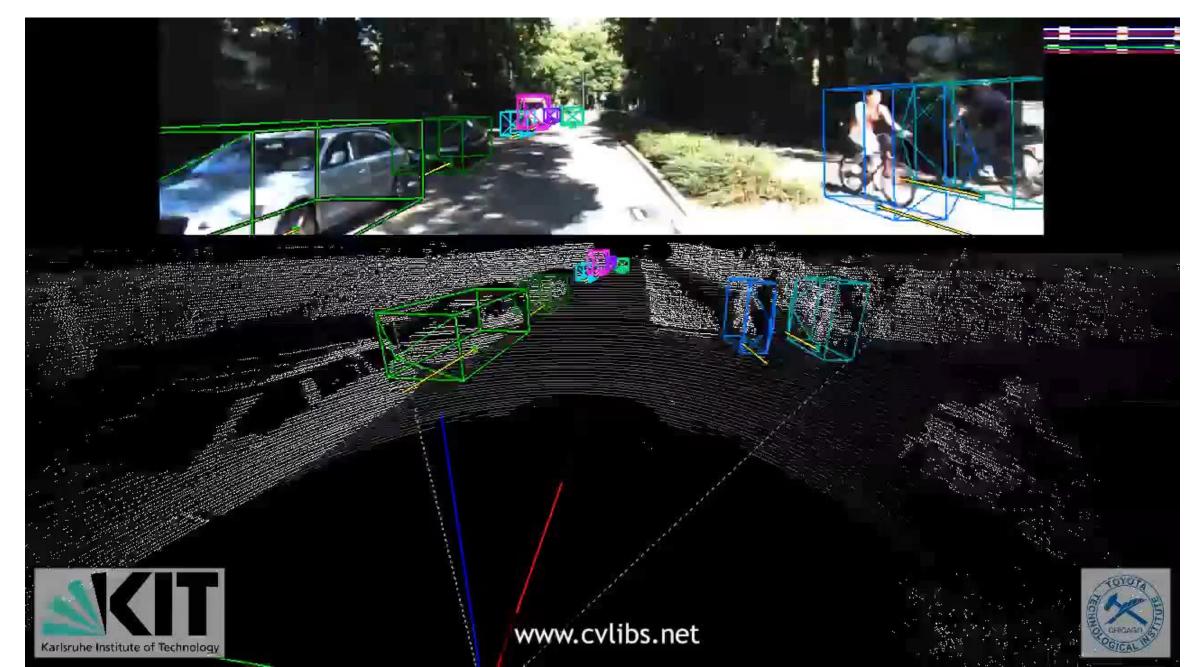

Mobile Robot Autonomy

- Mobile robot autonomy is a research area relying on tools from:
 - Computer Vision & Signal Processing: to deal with real-world signals in real time (e.g., filtering sound, convolving images, recognizing objects)
 - Probability Theory & Estimation Theory: to deal with uncertainty caused by sensor and actuator noise, computation and communication delays, and environment changes and estimate robot and world states
 - Optimization Theory: to plan the best robot behavior according to a suitable performance criterion
 - Control Theory: to execute the planned robot actions
 - Machine Learning: to improve the models and performance based on data (supervised, self-supervised, unsupervised, and reinforcement learning)

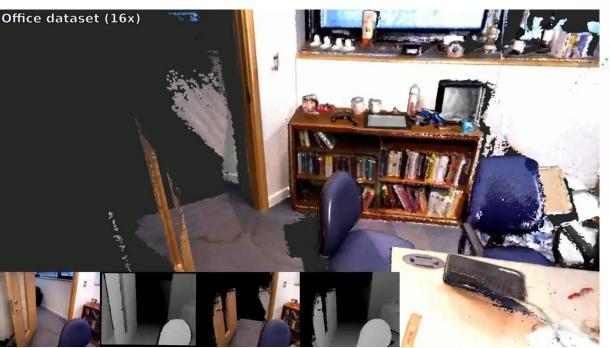

Robot Autonomy

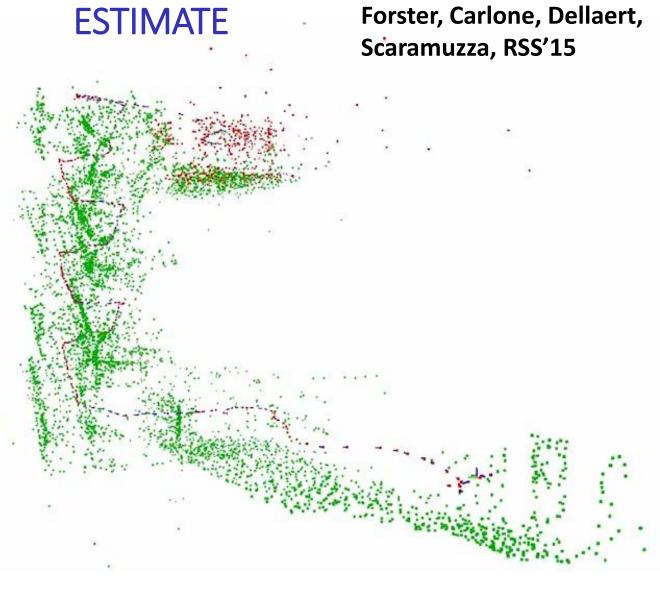

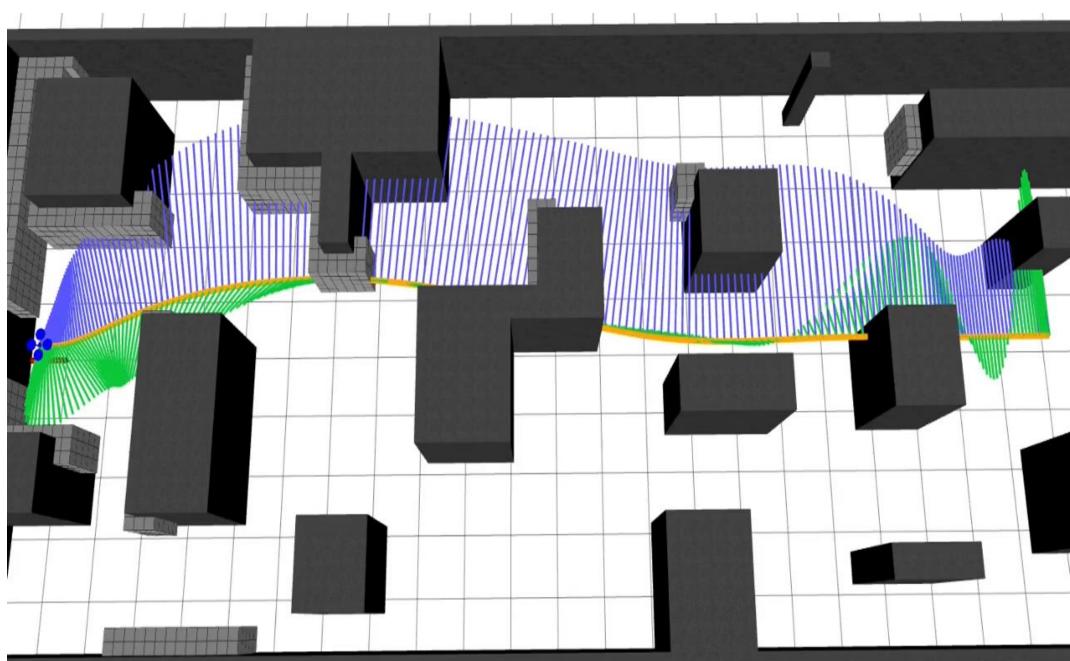

Whelan, Leutenegger, Salas-Moreno, Glocker, Davison, RSS'15

ECE 276A: Sensing & Estimation in Robotics

- The course will cover:
 - Sensing: image formation, projective geometry, rotations, features, optical flow
 - **Estimation**: probabilistic models, maximum likelihood estimation (MLE), Bayesian estimation, simultaneous localization and mapping (SLAM), hidden Markov models

- Course website: https://natanaso.github.io/ece276a
 - Schedule, reading materials, and assignments
 - Grades: GradeScope (SIGN UP!)
 - Discussion: Piazza (SIGN UP!)
 - Office hours/TA sessions: TBD
- References (optional):
 - State Estimation for Robotics: Barfoot
 - Probabilistic Robotics: Thrun, Burgard & Fox
 - An Invitation to 3-D Vision: Ma, Kosecka, Soatto & Sastry
 - Bayesian Filtering and Smoothing: Sarkka

A Warning About Prerequisites

- This is a challenging graduate course
- I want everyone to learn about robotics, so the prerequisites are not strictly enforced
- As graduate students, I expect you to be mature and carefully evaluate whether you are prepared to take the course
- Prerequisites:
 - **Probability Theory**: if you have not had a good course on probability theory it is too early to take ECE276A
 - Linear Algebra: if you have not had a good course on linear algebra, it is too early to take ECE276A
 - **Programming experience**: if you have not done programming projects of reasonable complexity before, it is too early to take ECE276A
- You will enjoy this course and learn a lot more if you have the right background
- Every year some students ignore this, overestimate their prior preparation or available time and have an unpleasant experience

Grading

- Assignments:
 - 3 theoretical homework assignments (16% of the grade total)
 - 3 programming assignments in **python** with project reports (18% of the grade each)
 - Final exam (30% of the grade)
- There is sufficient time to complete every assignment if you start <u>early</u>
- Late submissions and deadline extensions will not be possible because our schedule is tight
 (1 week background review, 3 weeks per project, final exam)
- Letter grades will be assigned based on the class performance, i.e., you do not need to and will
 not be able to get everything right in order to get a good grade
- Piazza is a great place for discussion, and I encourage you to use it
- In addition to asking questions, responding to others on Piazza is a great way to strengthen your knowledge

Collaboration and Academic Integrity

- Every assignment in this course is <u>individual</u>
- You are encouraged to discuss the assignments with other students in general terms but the work you do and turn in should be completely your own
- An important element of academic integrity is fully and correctly acknowledging any
 materials taken from the work of others provide references for papers and
 acknowledge in writing people you discuss the assignments with

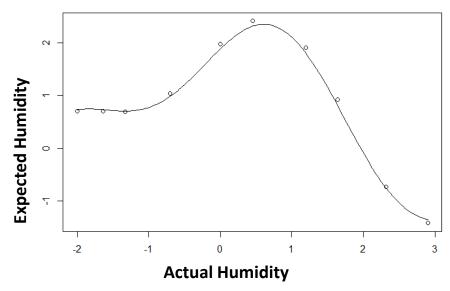

Cheating will not be tolerated

 Instances of academic dishonesty will be penalized via grade reduction and may be referred to the Office of Student Conduct for adjudication

Project Report: Suggested Structure

- 1. Introduction: brief discussion of what the problem is and why it is important It is important to monitor the humidity of plants and choose optimal watering times. In this paper, we present an approach to select the best watering time in the week from given historical humidity data.
- **2. Problem Formulation**: brief rigorous mathematical statement of the problem, not the solution! Let $f: \mathbb{R} \to \mathbb{R}$ be the average historical weakly humidity. **Problem**: Find a watering time $t^* \in \mathbb{R}$ such that $t^* = \underset{t}{\operatorname{argmin}} f(t)$
- **3. Technical Approach**: description of the ideas, equations, algorithms used to solve the problem The minimum of a function appears at one of its critical points $\{s \in \mathbb{R} \mid f'(s) = 0\}$. We find all the roots of f' and select the smallest one as the optimal watering time.
- 4. Results: figures showing qualitative and quantitative performance supported by discussion of what was successful and what fails

 The method performs well as shown in Fig. 1. The performance could be improved if real-time humidity measurements are used to update f.

Learning Navigation Costs from Demonstration via Differentiable Planning

Department of Electrical and Computer Engineering University of California, San Diego La Jolla, U.S.A. tiw 161@eng.ucsd.edu

Abstract—This paper focuses on learning cost functions that capture desirable behavior in tasks demonstrated by an expert. In a task such as autonomous navigation in unknown environments, a task such as autonomous navigation in unknown environments, it is possible to obtain sequences of observations (e.g., images), states (e.g., poses), and control inputs but not direct queries of the underlying task-specific cost function. Hence, it is necessary to design a planning algorithm that, depending on the current to design a planning algorithm that, depending on the current cost representation, computes a contral policy and propagates its error with respect to the demonstrations back to the cost representation. Our contribution is a probabilistic environment representation for local observation updates and cost function design, and a differentiable planning algorithm that performs state expansions only on a subset of promising states. Our complete model can be trained end-to-end and improves upon

Value Iteration Networks and the Dyna-Q algorithm.

Index Terms—Inverse Reinforcement Learning, Differentiable Planning, Cost Learning

I INTRODUCTION

Autonomous robot systems increasingly require operation in unstructured, partially known, and dynamically changing environments. One core challenge for safe and robust navigation is that the true cost function of a navigation task, requiring safe, dynamically feasible, and efficient behavior, is generally not known while expert demonstrations can be utilized to uncover the underlying cost function [1], [2]. In addition, humans and animals can navigate successfully with partial knowledge of the environment and adapt when facing new obstacle configuration based on prior experience. Motivated by this observation, we focus on learning a cost function from demonstration that is not universally accurate over the state and control space but rather captures task-relevant information and leads to desirable behavior.

Our main contribution is an end-to-end differentiable model that combines a cost function representation and an efficient planning algorithm (see Fig. 1). The novelty of our approach is that the proposed model is fully differentiable, which allows using gradient-based optimization to improve the parameterized cost function. Our experiments show that the end-to-end differentiable model learns task-specific cost functions and improves upon Value Iteration Networks (VIN) [3] and the Dyna-Q algorithm [4] by handling partial and noisy observations. In summary, we offer the following contributions:

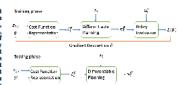

Fig. 1: Architecture for learning cost function representations from demonstrations via differentiable planning. During training, the goal is to learn a cost function parameterization θ based on demonstrations, consisting of states x1:4, controls $u_{1:t}^*$, and partial observations $z_{1:t}$, so that a control policy generated based on the learned cost incurs minimum loss $\mathcal{L}(\theta)$. Both the cost function representation $\hat{c}^{\theta}_{\epsilon}$ and the control policy π_{\star}^{θ} need to be differentiable with respect to θ for error backpropagation. During testing in a new environment, online observations $z_{1:t}$ and the trained parameters θ^* provide the cost function necessary to generate a control policy.

- · A cost function representation that incorporates a logodds occupancy representation of the environment, updatable using a parameterized observation model
- An efficient planning algorithm, which performs local convolutional operations encoding Bellman backups only on a subset of promising states. We guarantee that the output policy is differentiable with respect to the input cost function
- · An end-to-end differentiable model that learns taskspecific cost functions from expert demonstrations by backpropagating policy performance loss through the planning algorithm and the cost representation.

II. PROBLEM FORMULATION

Consider a robot navigating in an unknown environment with the task of reaching a goal state $x_g \in X$. Let $x_t \in X$ be the discrete time robot state. For a given control input u, ∈ U, the robot state evolves according to known deterministic dynamics: $x_{t+1} = f(x_t, u_t)$. Let m^* be a function

Abstract—This paper considers a non-cooperative two-player game modeling the problem of adversarial information acqui-sition in robotics. Each robot is equipped with a sensor, and is tasked with choosing control inputs that maximize an information (e.g. entropy) about the other player, while keeping its own state as uncertain to the other player as possible, subject to the available sensors. This adversarial information gathering problem has applications in surveillance, or search-and-rescue missions where the agent whose state is to be estimated may try to actively avoid the sensing robot. We formulate the problem of adversarial information acquisition, and provide an initial solution based on a variant of Monte Carlo Tree Search for

I INTRODUCTION

and-rescue applications, where the agent to be found is mobile,

dynamics of pursuit-evasion in mobile robotic settings[3]. abilistic frameworks which consider the expected case. A common theme in the pursuit-evasion literature is the objective of reducing the distance to the evader to zero, or forcing the evader into a sensing footprint. In contrast, our problem is formulated using a probabilistic approach which optimizes an information theoretic quantity, namely entropy, about the distribution of the target to be tracked. Rather than closing distance to the target, our approach aims to produce the best estimate of the target's state, subject to the sensors available. Our previous work considers the information acquisition problem for target tracking [1], however this work assumes that the target being tracked moves independently of the sensing robot, and crucially is not trying to actively evade the sensing robot. In this work, the problem formulation is symmetric in the sense that the adversary is trying to maximize information gained about us, and also minimize the information we can

We also draw attention to some biological inspiration for this problem. Motion camouflage [9] is a strategy utilized by dragonflies, which enables them to capture their prey by minimizing the optical flow of their motion. Mischiati and Krishnaprasad [8] consider the problem of mutual motion camouflage, where two agents each pursue each other, but attempt to maintain a constant bearing to avoid detection by the other agent. Our problem is related, but rather than considering pursuit-evasion, we consider the dynamics of an adversarial information gathering game.

In the most general case, the information acquisition game proposed is a stochastic game and is difficult to solve. McEneaney [7] discusses a class of stochastic games with finitedimensional solutions and dynamic programming algorithms In this paper, we consider the problem of two robots to solve them. With some assumptions on the motion and interacting in an adversarial game where each robot attempts observation models of the agents in our game, the problem to estimate the state of its adversary, while keeping its own can be simplified to a deterministic game. McEneaney [6] state hidden. This problem can have applications in search-introduces a curse-of-dimensionality free max-plus method for deterministic game problems, which is likely to be very and actively evades the sensing robot. In these problems, it is applicable to the linear Gaussian version of the informationimportant to both accurately localize the target agent, while theoretic game introduced here. Additionally, Grünwald and keeping one's own state hidden so that the target's ability to Dawid [4] present a game-theoretic argument that maximizing entropy and minimizing worst-case expected loss are duals There is much prior work in the literature concerning the of each other. A comprehensive treatment on adversarial reasoning, is provided in the book by Kott and McEneaney Approaches to the pursuit-evasion problem are split between [5]. The approach taken in this work is a variant of Monte considering the worst-case evader (adversary), and using probpresent the details of this approach in Sec. III.

II PROBLEM FORMULATION

Consider a two-player partial information game with simultaneous moves. Each player $i \in \{1,2\}$ has a state $x_{i,t}$ that evolves according to the following motion model:

$$x_{i,t+1} = f_i(x_{i,t}, u_{i,t}, w_{i,t})$$
 (1)

where $u_{i,t} \in U_i$ is a finite space of admissible moves (control inputs) and $w_{i,t}$ is a random variable specifying the motion noise. Player i can observe its own state $x_{i,t}$ and chooses its moves with the objective of tracking the evolution of the state of the other player. Each player is equipped with a sensor used to collect information about the other player according to the following observation model:

$$z_{i,t} = h_i(x_{i,t}, x_{j,t}, v_{i,t})$$

Active Object Recognition via Monte Carlo Tree Search

Mikko Lauri, Nikolay Atanasov, George J. Pappas, and Risto Ritala

Abstract—This paper considers object recognition with a camera, whose viewpoint can be controlled in order to improve the recognition results. The goal is to choose a multi-view camera trajectory in order to minimize the probability of having misclassified objects and incorrect orientation estimates. Instead of using offline dynamic programming, the resulting stochastic optimal control problem is addressed via an online Monte Carlo tree search algorithm, which can handle various constraints and provides exceptional performance in large state spaces. A key insight is to use an active hypothesis testing policy to select camera viewpoints during the rollout stage of the tree search.

I. INTRODUCTION

The goal of this paper is to choose a sequence of views for an RGB-D camera in order to identify the class and orientation of an object of interest (see Fig. 1). Unlike many existing approaches, which consider a next-best-view problem [1], [2], [3], we plan a multi-view camera trajectory to minimize the probability of having misclassified objects and incorrect orientation estimates. In previous work [4], we addressed a orientations for each class $c \in C$. For notational convenience, partially-observable Markov decision process. A point-based approximate solver [5] was used to obtain a non-greedy policy offline. Since repeated observations of the object from the same viewpoint provide redundant information, it is desirable to disallow viewpoint revisiting. The drawback of computing a policy offline is that revisiting and occlusion constraints are hard to incorporate and if the environment were to change, the computed policy would no longer be useful. The idea of this paper is to apply Monte Carlo tree search (MCTS, [6], [7]) to the active object recognition problem. MCTS is a best-first online planning approach which can handle various constraints and has exceptional performance in large challenging domains such as game solving [8], [9] and belief-space planning in to learn the probability density function (pdf) $q(\cdot \mid x, H_i)$ robotics [10], [11], [12].

II. PROBLEM FORMULATION

Let the camera pose at time t be $x_t \in X \subset SE(3)$, where Xis a finite set of viewpoints on a sphere centered at the object's location (see Fig. 1). At time t, the camera can move to any of the viewpoints in X and pays a cost $g(x_{t-1}, x_t)$ which captures the energy expenditure. Let the true (unknown) class of the observed object be $c \in C$. We formulate hypotheses about the class and orientation of the object:

H(c,r): the object class is $c \in C$ with orientation $r \in \mathcal{R}(c)$,

M. Lauri and R. Ritala are with the Department of Automation Science and Engineering, Tampere University of Technology, P.O. Box 692, FI-33101, Tampere, Finland, {mikko.lauri, risto.ritala}@tut.fi.
N. Atanasov and G. Pappas are with GRASP Lab, University of Pennsylvania, Philidelphia, PA 19104, USA, {atanasov, pappasg}@seas.upenn.edu. This work was supported by TernSwarm, one of six centers of STARnet, a Semiconductor Research Corporation program sponsored by MARCO and DARPA

Fig. 1: Setup for the active object recognition problem. The camera position is restricted to a set of viewpoints (green) on a sphere centered at the object's location. The task is to choose a camera control policy, which minimizes the movement cost and the probability of

Fig. 2: An example set of hypotheses about the class and orientation

where $\mathcal{R}(c) \subset SO(3)$ is a small finite set of discrete similar stochastic optimal control problem by casting it as a let i = 1, ..., M be an enumeration of the set $\{(c, r) \mid c \in A\}$ $C, r \in \mathcal{R}(c)$ and denote the hypotheses by H_i (see Fig. 2).

Offline, a 3-D model database is used to train a viewpointpose tree [4] by extracting point clouds from views on a sphere around each model. A set of Fast Point Feature Histograms [13] is extracted from each point cloud and the clouds are arranged in a tree structure according to their feature similarity (see [4] for details). Given a query point cloud, the bestmatching cloud from the tree carries information about the class and orientation of the observed object and about the quality of the feature match. Thus, the tree provides an observation $z_t \in \mathcal{Z}$, consisting of the class, orientation. and confidence score of the top match. The model database is used of z conditioned on any camera viewpoint $x \in \mathcal{X}$ and any hypothesis H_i , i = 1, ..., M.

Problem. Given a camera pose $x_0 \in X$, a prior $p_0 \in [0, 1]^M$ on the true hypothesis H_i , and a planning horizon $T < \infty$. choose a sequence of functions $\mu_t : (Z \times X)^{t+1} \to X$ for t = 0, ..., T - 1, which minimizes the average movement cost and the probability of an incorrect hypothesis:

$$\begin{aligned} & \min_{\mu_{0:T-1}} \frac{1}{T} \sum_{t=1}^{T} g(x_{t-1}, x_t) + \lambda Pe(T) \\ & \text{s.t. } x_{t+1} = \mu_t(z_{0:t}, x_{0:t}), \quad t = 0, \dots, T-1, \\ & x_{t+1} \notin \{z_{0:\dots}, x_t\}, \quad t = 0, \dots, T-1, \\ & z_t \sim q(\cdot \mid x_t, H_i), \quad t = 0, \dots, T, \\ & p_t = b(p_{t-1}, z_t, x_t), \quad t = 1, \dots, T, \end{aligned} \end{aligned}$$

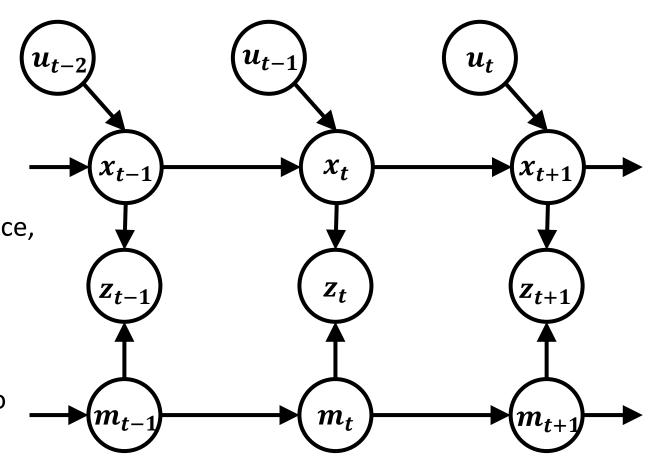

¹After a hypothesis is chosen, the discrete orientation estimate can be refined by aligning the observed object surface to the corresponding model

Structure of Robotics Problems

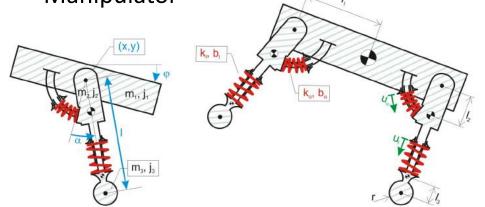

- **Time:** *t* (discrete or continuous)
- Robot state: x_t (e.g., position, orientation, velocity)
- Environment state: m_t (e.g., map of free space, locations of objects)
- Control input: u_t (e.g., quadrotor thrust and torque)
- Observation: z_t (e.g., image, laser scan, radio signal, inertial measurements)
- Motion Model: $p(x_{t+1}|x_t,u_t)$ --- describes the motion of the robot to a new state x_{t+1} after applying control input u_t at state x_t
- Observation Model: $p(z_t|x_t,m_t)$ --- describes the observation z_t of the robot depending on its state x_t and the map m_t of the environment

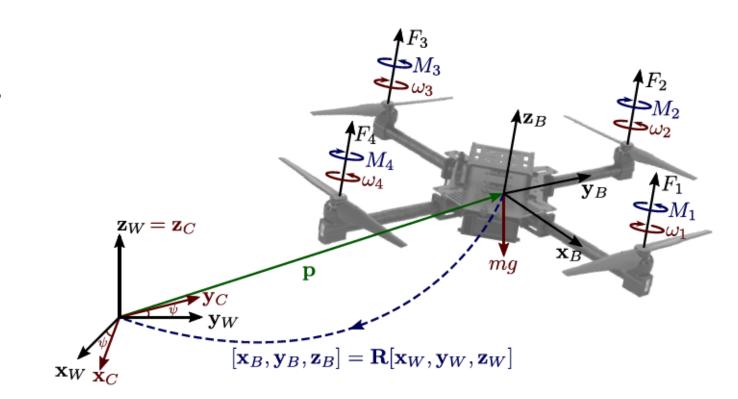

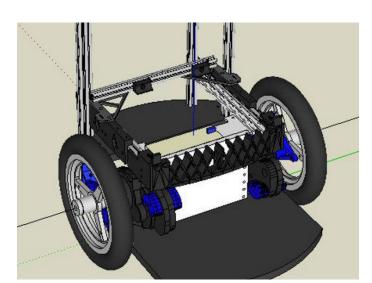

Motion Models

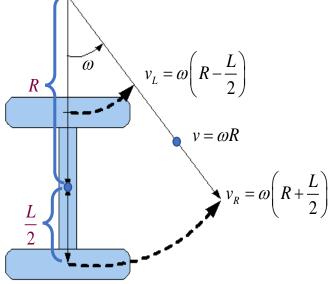

- A motion model describe the kinematics or dynamics of the robot state x_t
- Wheeled robots:
 - Differential drive (roomba)
 - Ackermann drive (car, bicycle)
- Aerial robots:
 - Fixed-wing aerial vehicle
 - Quadrotor aerial vehicle
- Legged and humanoid robots:
 - Quadruped

Manipulator

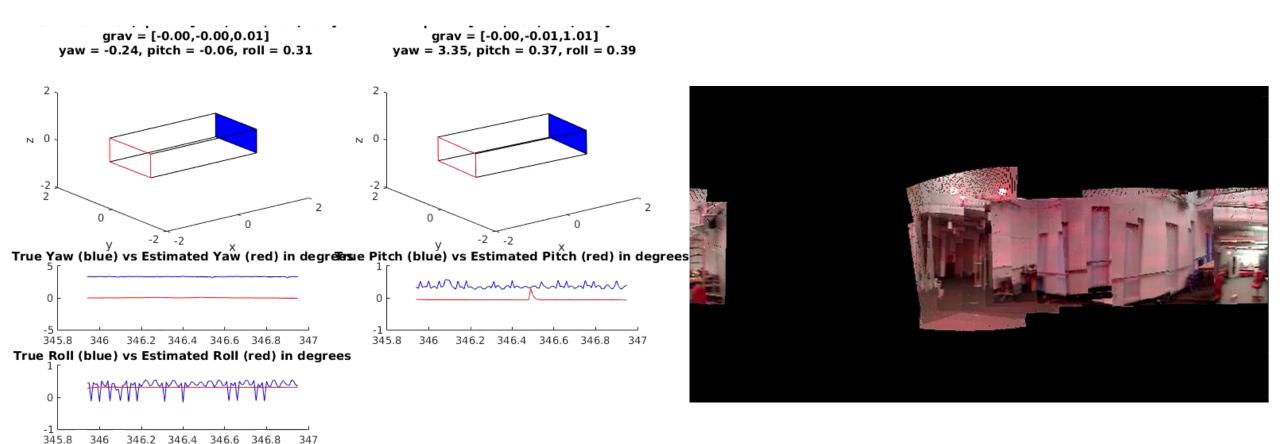

Observation Models

- **Position Sensor:** directly measures position (e.g., GPS, laser scanner, IR sensor, RGBD camera)
- **Velocity/Acceleration/Force Sensor**: measures linear acceleration or angular velocity or pressure or force (accelerometer, gyroscope, inertial measurement unit (IMU), tactile sensor)
- Bearing Sensor: measures angles (e.g., magnetometer, camera, microphone)
- Range Sensor: measures distances (e.g., radio)

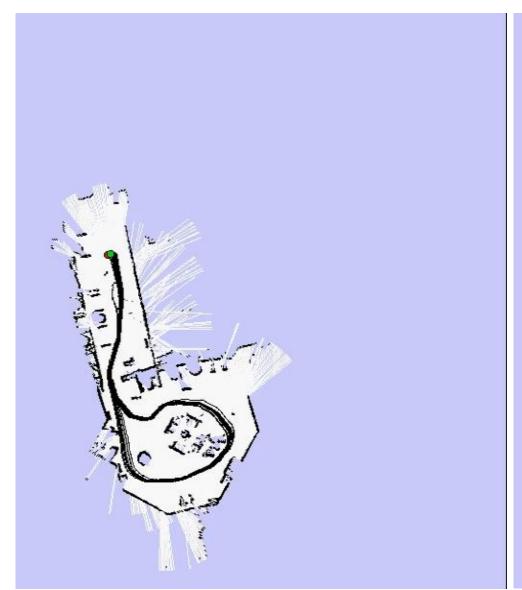

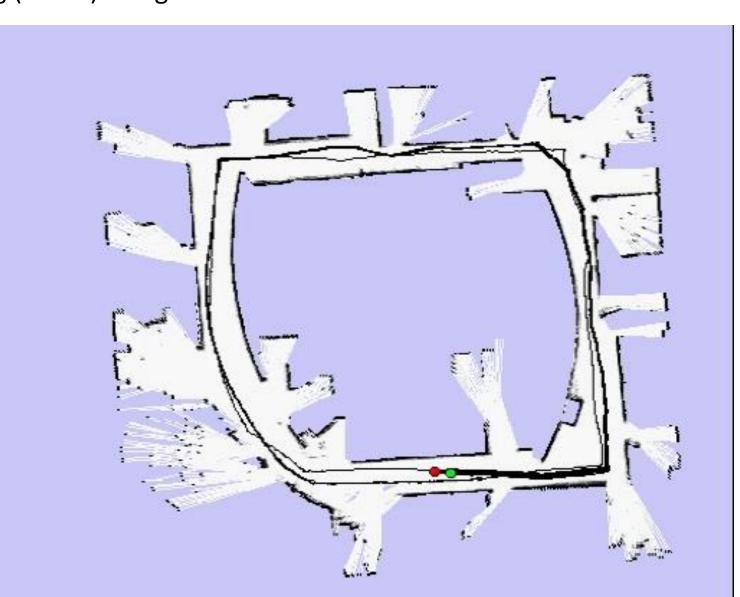

Project 1: Orientation Tracking

 Use constrained gradient descent to track the 3D orientation of a rotating body using IMU measurements and construct a panorama using RGB images

Simultaneous localization and mapping (SLAM) using a lidar scanner

Project 3: Visual Inertial SLAM

• Kalman filter tracking of the 3D pose of a moving robot based on IMU and camera measurements
